TECHNICAL NOTE 2852

AN INVESTIGATION UTILIZING AN ELECTRICAL ANALOGUE

OF CYCLIC DE-ICING OF A HOLLOW STEEL PROPELLER

WITH AN EXTERNAL BLADE SHOE

By Carr B. Neel, Jr.

SUMMARY

A study has been made of the heat requirement for the cyclic de-icing of hollow steel propellers fitted with external blade heating shoes. Solutions to the equations for the heat flow in cyclic heating of propellers were obtained, using an electrical analogy. The study showed how the energy requirement for propeller de-icing with existing blade shoes could be decreased, and illustrated the effect of blade-shoe design on the energy requirement. It was demonstrated, for example, that by increasing the heating intensity and decreasing the heating period from those currently used the energy requirement could be decreased in the order of 60 percent. In addition, it was shown that heating requirements could be decreased further, by as much as 60 percent, through proper design of the shoes. The investigation also showed the energy requirement to increase with decreasing liquid-water content and air temperature. Uncertainties as to the exact values of convective heat-transfer coefficient prevailing over the surface of the blade and ice layer resulted in uncertainties of approximately proportional magnitude in the values of required heating intensity.

INTRODUCTION

Propeller ice protection for aircraft is generally provided by electrical heating. In the development of external heating shoes, emphasis was placed primarily on the determination of the heating intensity required. Preliminary tests indicated power requirements for continuous heating to be so large that cyclic operation, with attendant power savings, was almost mandatory. Subsequent tests (reference 1) included some variation in cyclic time and other pertinent factors, but were mainly concerned with heating pattern and heating intensity for one blade and shoe configuration.

Tests of cyclically operated propeller blade shoes have been too limited in scope to provide a comprehensive picture of the effects of various parameters on blade-shoe performance. Electrical simulation of the flow of heat from the heating element of a blade shoe during cyclic operation offered a means for obtaining more complete data on cyclic de-icing. By use of an electrical analogy, a large range of configurations and operating conditions could be covered readily. Such a study of a similar problem was first made by Tribus (reference 2). This work was limited in its scope, reproducing portions of the data obtained in reference 1 and covering only the general aspects of the problem.

The present study is the first phase of a general investigation of the cyclic de-icing of propellers protected with heater elements installed on either the external or the internal surface of the blade. This report concerns heating shoes mounted externally on a hollow steel blade. The purpose of this investigation is twofold: (1) to present data which will show the operator of existing propeller blade shoes how to obtain efficient operation under various meteorological conditions, and (2) to indicate to the designer of blade shoes the factors influencing proper design and selection of insulating materials. Quantitative values are given in both cases. An electrical analogue was used in the study to provide a solution to the heat-flow equations representing transient heat flows in a cyclically heated propeller and blade-shoe combination.

FACTORS INFLUENCING HEATING REQUIREMENTS
FOR CYCLIC DE-ICING

In order to aid in the understanding of the problem of cyclic propeller de-icing, the factors governing heating requirements for cyclic de-icing will be mentioned. Among the important variables influencing the heating requirements are the duration of the heating period and the heating intensity supplied to the blade shoes. It would be expected that as the heating period is decreased, the heating intensity must be increased to maintain de-icing protection. Also, the meteorological conditions (liquid-water content and air temperature) and flight conditions (airspeed and altitude) affect the energy requirements. The thickness and thermal conductivity of the insulation material used in the construction of the blade shoes are additional factors. The influence on propeller heating requirements of variations in each of these parameters, with the exception of airspeed and altitude, was studied.

DESCRIPTION OF EQUIPMENT

Electrical Analogue

The electrical analogue used in the study of cyclic de-icing is shown in figure 1. The analogue consists essentially of a network of electrical resistances and capacitances connected in such a manner as to simulate a thermal circuit. In the electrical circuit, electrical resistance and capacitance represent thermal resistance and capacitance, current flow represents heat flow, and voltage difference represents temperature difference. The resistances of the analogue network consist of potentiometers connected as rheostats, while the capacitances consist of condensers which were connected to obtain the desired values. The method of utilizing an electrical analogy for the solution of transient heat-flow problems is thoroughly treated in references 3, 4, and 5.

Special Circuits

Intermittent application of current, representative of cyclic heating, was accomplished by means of a switching system actuated by a synchronous electric motor. Since the power input to the blade shoe is constant during the heating part of the cycle, a source of constant current was provided for the electrical simulation of power input to the heater element. Additional constant-current circuits were arranged to represent the application of heat at the blade surface resulting from aerodynamic heating and release of the heat of fusion of the supercooled drops impinging on the blade surface as they solidified to ice.

To represent the periodic accumulation of ice on the blade shoe, relay circuits were employed which switched in resistors and condensers representing the equivalent values of thermal resistance and capacitance of the ice layers. The continuous growth of the ice formation was represented in the analogy, using the assumption that the ice built up in three layers of equal volume throughout each cycle. Periodic precharging of these condensers, just prior to their connection into the circuit, to represent the increase in temperature of the ice layers due to the addition of aerodynamic heating and release of the heat of fusion of the ice upon formation was achieved by means of a circuit utilizing the constant-current power supply and the ice-accumulation relays. These relays were synchronized with the cyclic heating through the same switching system.

Because during application of heat certain portions of the blade-shoe surface underneath the ice formation reached the melting point of ice before release of the formation, special circuits, termed "heat-of-fusion circuits," were provided which held the surface temperature of these regions at a constant voltage representing 32° F until release of

the ice accumulation. This represented the absorption of heat by the
ice layer during the melting process.

Measuring Equipment

A recording oscillograph, shown in figure 2, was used to record the
voltage changes representative of the temperature changes occurring dur-
ing cyclic heating. The same instrument was utilized to measure the
current flow representative of heat flow.

CHARACTERISTICS OF PROPELLER, BLADE SHOE, AND ICE FORMATIONS

Configuration and Characteristics of Propeller Blade

The propeller selected for this study is typical of those currently
in use on transport airplanes. The aerodynamic and physical character-
istics of the bare propeller blade (without blade shoes) are given in
figure 3. The symbols presented in this figure and those used elsewhere
in the report are defined in appendix A. Cross sections of the blade
with shoes installed showing the section contours at the radial stations
analyzed are presented in figure 4. The values for the properties of
blade-metal density, specific heat, and thermal conductivity used in the
study are given in table I.

Configuration and Characteristics of Blade Heating Shoe

Study of conventional blade shoe.- A blade shoe typical of those
currently in use was simulated for this phase of the investigation. The
shoe was assumed to extend from the blade shank to the tip. As illus-
trated in figure 4, the shoe extended chordwise a distance of about
1-3/4 inches on both sides of the blade from the leading edge for the
entire length of the shoe. The insulating material was considered to
consist of layers of rubber 0.03 inch thick above and below the heater
element. Values taken for the physical properties of the insulating
material are shown in table I. A uniform chordwise heating distribution
was assumed.

Study of effects of variations in characteristics of blade shoe.-
The effects on heating requirements of variations in the physical proper-
ties and thickness of the blade-shoe insulation material were studied for
one radial station at one meteorological and operating condition. The
program for the systematic study of these effects is presented in the
following table. Multiplying factors for the properties of the insulation

material are based on layers of rubber 0.03 inch thick above and below the heater element.

Effect studied	Location of insulation relative to heater	Multiplying factor for thermal resistance,R	Multiplying factor for thermal capacity,C	Physical significance
Variations in properties for insulation above heater element (insulation below heater 0.03-inch rubber)	Above	0.5	1	
		.2	1	
		0	1	
		0	0	No insulation
		1	0	
		.5	.5	1/2 thickness
Variations in properties for insulation below heater element (insulation above heater 0.03-inch rubber)	Below	2	1	
		5	1	
		10	1	
		∞	0	Perfect insulation
		1	0	
		2	2	2 × thickness
Variations in properties for insulation above and below heater element	Above	0	0	No insulation above, perfect insulation below
	Below	∞	0	
	Above	0	0	No insulation (heater on blade-metal surface)
	Below	0	0	
	Above	.5	.5	1/2 thickness above, 2 × thickness below
	Below	2	2	

Configuration and Characteristics of Ice Formations

The configurations of the ice formations assumed are illustrated in figure 4. The chordwise extent of the formations was based on calculations of the farthest point aft of water-drop impingement, using the data of reference 6, while the shape of the accretions was based on photographs of actual ice formations and experience with the accretion of ice on

propeller blades. Table I presents the values of the physical properties
of the ice layers used in the investigation.

Division of Blade, Shoe, and Ice Formations for Analogue Study

In the analogue study, the blade, shoe, and ice formations were
divided into regions throughout which conditions were assumed constant.
The blade was divided radially at 4 stations and chordwise into 11 seg-
ments, with the smallest divisions in the leading-edge region at the
location of the blade shoe. (See fig. 4.) Each segment was subdivided
into one layer representing the blade metal, six layers (three on each
side of the heating element) representing the shoe material, and three
layers corresponding to three ice increments.

OPERATING AND METEOROLOGICAL CONDITIONS
SELECTED FOR ANALOGUE CALCULATIONS

Airplane Operating Conditions

The airplane operating conditions selected for all the tests were
chosen as being typical of those for transport airplanes currently in
operation and are given as follows:

Forward true airspeed	300 mph
Propeller rotational speed	1100 rpm
Pressure altitude	20,000 feet

Blade-Shoe-Heater Operating Conditions

A total-cycle-time duration of 80 seconds was maintained for all
tests of cyclic heating. Three ratios of duration of heating period to
total-cycle time were investigated, as follows:

Cycle ratio	Time on (sec)	Time off (sec)
1 to 4	20	60
1 to 8	10	70
1 to 16	5	75

Meteorological Conditions

The basic meteorological conditions selected were:

> Liquid-water content   0.1 gm/m^3
> Water-drop diameter   15 microns
> Free-air temperature -12° F

Limited studies also were made at values of liquid-water content of 0.2, 0.4, and 0.6 gram per cubic meter, and at air temperatures of 0° and -20° F. The liquid-water content of 0.1 gram per cubic meter was selected as a reasonable low value since low values of water content, combined with low air temperature, represent the most severe conditions for a propeller cyclic de-icing system. The air temperature of -12° F was computed from the data of reference 7, and was based on the probability of encountering a lower value of air temperature once in 1000 icing encounters for the conditions of 0.1 gram per cubic meter and 15 microns diameter.

TEST PROCEDURE

Arrangement of Analogue Circuits to Simulate
Cyclic De-Icing of a Propeller

Appropriate values of electrical resistance and capacitance were placed on the analogue to simulate the thermal circuit of the propeller blade. Preliminary calculations and tests indicated that radial heat conduction was negligible. Therefore, independent circuits were set up for each propeller station. The heat-transfer equation used in the evaluation of the effective thermal resistance from the ice surface to the surrounding air and the equilibrium temperature of the ice surface is developed in appendix B. The method of reference 8 was used to compute the values of heat-transfer coefficient which determine the values of the air thermal resistance. In the computation of electrical values, a ratio of analogue time to actual time of 1 to 50 was taken to allow the use of condensers of a size sufficiently small for insertion on the analogue panels, and to allow the data to be obtained rapidly. Thus, a 1-second increment of time on the analogue represented a 50-second interval of time on the propeller blade.

Prior to gathering the transient-temperature data, the values of equilibrium surface temperature were set for each of the blade segments. In the region of the ice cap, the heat-of-fusion circuits were set for all segments but the one exhibiting the smallest temperature rise. With the blade shoe operating cyclically, the heater input intensity was adjusted so that the surface temperature of this segment just

reached 35° F at the instant of termination of the heating cycle. It
was assumed that this would assure a complete release of all portions of
the ice formation.

Recording of Data

With the analogue values properly adjusted, separate records were
taken of the temperature variations of the blade-shoe surface, heater
element, and blade metal, and variations of the heat flow from the heater
element during simulated cyclic de-icing of the propeller. Curves also
were obtained of the variation of the heater-element temperature with
time during the initial period of a continuous application of heat.

RESULTS

Cyclic-Heating Data

Typical data from analogue.- Curves representative of the data
obtained from the analogue are shown in figures 5 and 6. Figure 5 pre-
sents, for one segment of the propeller, the temperature variations for
the blade-shoe surface, heater, and blade metal, and the variations in
magnitude and direction of the heat flow from the heater element. Typi-
cal temperature variations for all segments of the exposed surfaces of
the blade and shoe are shown in figure 6 for one propeller station.
These data can be considered to be typical for the other stations as well.

Effects of variations in operating conditions for one blade-shoe
configuration.- The blade-shoe configuration simulated for these tests
consisted of the conventional shoe previously described in figure 4 and
table I, which was intended to be typical of those currently in use. The
results of tests to determine the effect of variations in the cyclic-
heating ratio and air temperature on the required heating intensity for
the four radial stations analyzed are shown in figure 7. For these tests
the liquid-water content was maintained at 0.1 gram per cubic meter.
Table II presents the maximum heater temperatures reached during opera-
tion under the above conditions.

Figure 8 gives the results of tests to illustrate the effect of a
variation in liquid-water content on the minimum value of air temperature
for which cyclic de-icing can be accomplished with a heating intensity
of 10 watts per square inch of blade-shoe-surface area and a duration of
heating time of 20 seconds. These data were obtained for radial station 48
only.

The results of an investigation at typical values of heating inten-
sity and cyclic ratio currently in use are shown in figure 9. This
figure indicates the minimum free-air temperature for which cyclic
de-icing can be achieved with a heating intensity of 8 watts per square
inch and a cyclic ratio of 20 seconds on and 60 seconds off, for one
value of liquid-water content.

Effects of variations in blade-shoe material and construction for
fixed operating conditions.- These tests were performed for the basic
meteorological conditions of 0.1 gram per cubic meter water content
and -12° F free-air temperature, and for radial station 48 only. Fig-
ure 10 illustrates the effect of variations in the thermal properties of
the insulation material above the heater element on the heating require-
ments as a function of heat-on time. Similar data for the insulation
layer below the heater element are presented in figure 11. Figure 12
shows the combined effect of variations in the properties for the insu-
lation layers both above and below the heater element. Further tests to
illustrate this combined effect are given in figure 13, which compares
the heating requirements for the conventional shoe and a shoe having dif-
ferent thicknesses of rubber insulation above and below the heater.

Effects of variations in heat-transfer coefficients.- As in the pre-
vious experiments, these tests were limited to station 48 and were con-
ducted for the conditions of 0.1 gram per cubic meter and -12° F. The
effect of a variation of ±20 percent from the calculated heat-transfer
coefficient on the heating requirements is shown in figure 14 for the
conventional shoe and a modified shoe.

Continuous-Heating Data

A typical curve of the initial heater-element-temperature change
resulting from a continuous application of heat is presented in figure 15.
Data showing the time required for the heater temperature to reach values
of 150°, 175°, and 200° F for continuous heating under the same operating
conditions as for cyclic heating (table II) are given in table III. These
data were obtained for the conventional blade shoe from curves similar to
that shown in figure 15. The values presented in this table would pro-
vide information applicable to the case of malfunctioning of the cycling
switch wherein excessive temperatures might cause failure of the blade-
shoe insulation.

DISCUSSION

As mentioned previously, the heating efficiency and resulting energy
requirement for a given blade shoe are dependent on the procedure followed

in the operation of the shoe. In addition, the design of the shoe and the selection of materials used in its construction can also influence its performance. Consequently, the results of this investigation have been examined from the viewpoints of both the operator and the designer.

Blade-Shoe Performance as Influenced by Variations in Operating Conditions

Effect of variation in duration of heating period.- From figure 7 it is evident that as the duration of the heating period is decreased, the required heating intensity for de-icing is increased. The required increase in heating intensity, however, is not proportionately as large as the decrease in heating period, resulting in a decrease in the over-all energy requirement for a decreased heat-on time. This effect is illustrated in figure 16, in which is shown the possible decrease in required energy as a function of heat-on time. The values of energy requirement are based on the product of heating intensity and heating time as obtained from figure 7. Figure 16 shows that by decreasing the duration of heating time from 20 seconds to 5 seconds, the energy requirement can be decreased by about 60 percent.

There are three factors which must be considered, however, before this saving can be effected. These are (1) the more rapid temperature rises in and under the heating shoe resulting from the increased heating intensity required for short heating periods, (2) the increased size of the ice accretions thrown from the blade because of longer heat-off time, and (3) the adaptability of a short cyclic heating time to the source of electrical power. The data in table II indicate that the maximum heater temperatures would not be excessive at heating intensities as high as 27 watts per square inch. In addition, the maximum temperature reached at the surface common to the blade and shoe was shown from the analogue data to be well below 100° F. Considering the second factor, the tolerable size of ice accretion is dependent upon conditions which are established by the particular installation, and may require some compromise on the part of the designer. Finally, the inclusion of a short heating time, such as a 1-to-16 cyclic ratio, for propeller heating with the other electrical demands for the airplane may or may not present the designer with a problem. For example, on a four-engine airplane with four-bladed propellers the successive heating of one blade at a time would provide a required cyclic ratio of 1 to 16. This procedure has the possible disadvantage of unbalancing the propeller if the removed ice accretions are large. If it is impractical to heat one blade at a time, the power supply would have to be used intermittently to maintain the 1-to-16 cyclic ratio, which defeats the purpose of the short heating time. Two solutions to this situation are: (1) to use the power supply for intermittent electrical de-icing of other components of the airplane, and (2) to develop an intermittent-duty generator, which should be considerably lighter than a continuous-duty generator of comparable output.

Effect of variation in free-air temperature.- Figure 7 shows that as the free-air temperature is decreased, the required heating intensity is increased. The effect of air temperature on required heating intensity is shown to have a dominant influence on the de-icing performance of blade shoes. The deviation of the curves for station 72 from the general pattern for the other three stations is due primarily to the increased equilibrium temperature at this station resulting from the higher velocity.

Effect of variation in liquid-water content.- The data of figure 8 show that as the liquid-water content is increased, the air temperature at which cyclic-de-icing protection is obtained with a given heating intensity can be decreased. From these results, it may also be stated that at any given air temperature the energy requirement for de-cing decreases as the water content increases. This characteristic of propeller cyclic de-icing is due (1) to the effect of the higher rate of release of the latent heat of fusion resulting from the more rapid rate of formation of ice at the higher values of water content, and (2) to the increased insulating effect of the thicker ice layer which forms at the higher water-content values. The feature of a decreasing energy requirement for cyclic de-icing with increasing water content was initially reported in reference 2, and is in contrast to the case of energy requirements for an ice-prevention system in which the surface temperature must be maintained continuously above the freezing point.

It is of interest that icing tunnel tests of cyclically heated stationary airfoils (references 9 and 10) showed practically no influence of variations in liquid-water content on the energy required for de-icing. It is believed that these data are not incompatible with the conclusions of the analogue study. The results from cyclically heated stationary airfoils cannot be compared with the case of cyclically heated rotating propellers, where the criteria for ice removal are considerably different. In the case of propellers, it is necessary only to raise the surface temperature to 32° F to obtain de-icing, since at this temperature the adhesion of ice decreases to zero (reference 11), and the aerodynamic and centrifugal forces remove the accretions. For wings, on the other hand, the aerodynamic forces provide the only means for shedding the ice accretions. This is an uncertain action and, as a result, the ice formations are not removed when the surface temperature reaches 32° F, but instead continue to absorb heat until removal finally occurs. In view of this additional energy input, it is reasonable that the energy-requirement variation with changes in liquid-water content for intermittently heated wings should lie somewhere between the variations for cyclically heated propellers (decreasing energy requirement with increasing water content) and continuously heated wings (increasing energy requirement with increasing water content).

It has been demonstrated that the power requirements for de-icing increase both with decreasing liquid-water content and with decreasing air temperature. Unfortunately, it is a characteristic of icing conditions

that as the air temperature decreases, the value of water content likely
to be encountered decreases also (reference 7). Thus, for the propeller
cyclic-de-icing system, the power requirements are doubly increased at
low air temperatures. There is some degree of compensation, however, in
that as the water content decreases, the necessity for de-icing also
decreases, inasmuch as the formations do not tend to become as large or
deleterious as at higher values of water content. The prevalent meteor-
ological conditions must be considered in the design and efficient oper-
ation of blade-heating shoes with adequate de-icing protection. It is
believed that the water-content values together with the air-temperature
values studied in this investigation provide a reasonable coverage of
such conditions.

Radial distribution of required heating intensity.- Curves of the
variation of heating intensity required for de-icing as a function of
radial station for the conventional blade-shoe configuration are pre-
sented in figure 17 for the case of a free-air temperature of -12° F.
These data show that the heat requirements decrease with increasing
radial station. This is a result of the increased aerodynamic heating
and rate of formation of ice caused by the higher velocities at the outer
radial stations. The higher rates of ice formation provide a more rapid
addition of heat from the latent heat of fusion of the ice, which, when
combined with the increased aerodynamic heating, more than compensates
for the increased heat loss resulting from the higher convective heat-
transfer coefficients prevailing over the outer radial stations.

The distribution of required heating intensity exhibited in figure 17
indicates that for the case of existing blade shoes, which generally have
a uniform heating distribution radially, the outermost regions of the
blade shoe would tend to be de-iced first. Thus, at incipient de-icing
failure of the innermost regions of the blade shoe, the outer stations
still would tend to shed ice, a condition which is aided by the higher
centrifugal forces in these areas. This point is substantiated by the
photographs of reference 1, which show the outer regions of the blade to
be cleared while the inner portions are covered with ice for a uniform
radial distribution of heat. This is a desirable characteristic, inasmuch
as it is the outer portions of the blade which develop most of the thrust
and consequently are affected most adversely by the formation of ice
(reference 12).

Examination of maximum-heater-temperature data.- The data presented
in table II, which shows the maximum heater temperatures reached during
cyclic de-icing, provide an indication of the feasibility of utilizing
the higher heating intensities for the shorter durations of heating time.
If the heater temperature should become excessive, the insulation material
surrounding the heater element could fail, resulting in electrical failure
of the blade shoe, with possibly more serious consequences. The data of
table II show the maximum heater temperatures to be fairly constant at
any given condition, regardless of the heating intensity. The maximum
temperature reached was 145° F at a heating intensity of 27 watts per

square inch with a 5-second heating period. This temperature is well below the failure temperature of the blade-shoe insulating materials currently in use. The highest heater temperatures occurred under the conditions of lowest air temperature, which required the highest heating intensities. It is obvious, of course, that if the heating intensity is adjusted for de-icing at a low air temperature, the maximum heater temperature will exceed the values presented in table II during operation at a higher air temperature. A similar situation would exist at values of liquid-water content greater than 0.1 gram per cubic meter.

The possible failure of the system used to cycle the power to the blade shoes presents a hazard, particularly at the higher values of heating intensity. If the cycling switch should become jammed, for example, allowing power to the blade shoe to be supplied for an indefinite period, the heater temperature may quickly exceed the allowable limit. Table III gives an indication of the amount of time the power could be applied continuously before certain operating temperatures would be exceeded. These data are intended to provide information which could be utilized in the design of a safeguard to protect the blade shoes in the event of occurrence of a cycling-system failure.

The maximum temperature of the blade-metal surface reached during cyclic heating is of importance if the temperature exceeds the allowable limit of the bonding agent used in the installation of the blade shoe. An examination of the data revealed that the maximum blade-metal temperature reached was 85° F, well below the maximum allowable temperature of bonding agents currently in use.

Blade-Shoe Performance as Influenced by Variations in Blade-Shoe Material and Construction

Effect of variations in insulation layer above heater element.- Figure 10 shows that as the thermal resistance and thermal capacity of the insulation layer above the heater element are decreased, the required heating intensity is decreased. For a conventional blade shoe, the effect of a decrease in resistance is much greater than a proportional decrease in capacity. For example, reducing the thermal resistance to zero results in a decrease in the required heating intensity of about 50 percent of that required with a 0.03-inch-thick layer of rubber, at a heat-on time of 5 seconds, whereas decreasing the capacity to zero results in a reduction in required heating intensity of only 15 percent for the same heating conditions. A saving in heating intensity and, hence, in required power of about 55 percent is possible for a 5-second heat-on time by eliminating the insulation layer completely.

Figure 18 presents an indication of the power saving possible by reducing the thermal resistance from the value for a rubber insulation layer 0.03 inch thick. This figure shows that substantial savings in

power are to be gained through reasonable reductions in the thermal resistance.

Effect of variations in insulation layer below heater element.- Figure 11 shows that as the thermal resistance of the insulation layer below the heater element is increased, the required heating intensity is · decreased. Likewise, the required heating intensity is decreased as the thermal capacity is decreased. As in the case of the insulation layer above the heater element of a conventional blade shoe, the effect of a change in resistance is considerably greater than a proportional change in capacity. A saving in required power of about 50 percent could be obtained with perfect insulation below the heater.

Figure 19 presents an indication of the power saving possible through increases in the thermal resistance from the value for a layer of rubber 0.03 inch thick. Again, considerable power savings can be effected by reasonable increases in the thermal resistance.

Effect of variations in the insulation layers both above and below the heater element.- Figure 12 illustrates the effect of combining the variations in the insulation layers both above and below the heater element. A curve is shown for the case of no insulation above the heater and perfect insulation below. This indicates the ultimate in design of an external blade shoe. In this case, all the heat delivered to the heater is being utilized to raise the temperature of the ice; none of the heat is being wastefully absorbed by the blade. This curve is nearly flat, displaying very little rise in required heating intensity with decrease in heat-on time. Obviously, the most efficient region of operation is at the shorter durations of heating time. By operating at a heating-time duration of 5 seconds, for example, the power requirement can be reduced to 38 percent of that necessary for a conventional shoe operating at the same heating time. This is representative of a reduction in total energy to only 14 percent of that required for the conventional shoe operating at 20-seconds heat-on time. The contrasting inefficiency of the conventional blade shoe is further illustrated in the transient heat-flow data of figure 5, in which it is shown that roughly half the total heat delivered flows into the blade during the heating phase of the cycle, leaving only about half the heat input to perform the function of removing the ice.

Figure 12 also shows the effect of reducing to zero the insulation resistance and capacitance beneath the heater element, with no insulation above the heater. This configuration is the equivalent of mounting the bare heater directly on the propeller blade, and would be approached in practice by the application of an electrically conductive film to the blade surface, a process which has been recently developed. With this configuration, considerable power may be saved over that required for a conventional shoe at heat-on times greater than 5 seconds.

Because of the problem of abrasion, it may not be feasible to allow the heater element to be exposed in the manner suggested. The abrasion problem, in fact, has led to the use of fairly thick layers of rubber above the heater for its protection (0.03 inch thick in the case of the conventional shoe simulated in this investigation). This is undesirable from the thermal standpoint, however. One possible solution to this problem lies in the development of a material with decreased thermal resistance and suitable abrasion-resistance characteristics.

A more immediate solution to the thermal problem alone would be to reduce the thickness of the layer of rubber insulation above the heater, as suggested by the data of figure 13. If the thickness of this layer is reduced by a factor of 2, the power requirement may be decreased about 25 percent. Additional power economy may be achieved by increasing the thickness of the layer of rubber under the heater element. The combined effect of utilizing a layer of rubber half the original thickness above the heater and twice the original thickness below is shown in figure 13 to reduce the power requirement about 30 percent. Protection of such a blade shoe from abrasion might be accomplished through installation of a thin strip of metal along the leading edge of the blade over the shoe. Tests to determine the thermal effect of such an abrasion strip 0.002 inch thick showed no increase in the heat requirements.

A further means of reducing the over-all energy requirements for propeller de-icing would be to reduce the chordwise extent of the blade shoe. It should be noted that such a procedure would be feasible only if the resulting coverage is sufficient to provide adequate protection, a factor which is determined by the chordwise extent of the ice accretion. In all of the blade-shoe configurations investigated embodying insulation under the heater, the required heating intensities were influenced negligibly by variations in the chordwise extent of the heater. In the case of the heater element mounted directly on the blade, however, chordwise heat conduction is sufficiently high that any reduction in heater width is reflected in an increase in the required heating intensity. The extent of this effect is illustrated in figure 12, in which is shown the heating-intensity curve for the case where the heater is reduced about 30 percent in width. Although the required heating intensity is increased, the total energy requirement is decreased by over 15 percent due to the reduction in area of the heater.

Blade-Shoe Performance as Influenced by Variations in Heat-Transfer Coefficients

The data of figure 14 show that changes in the values of the convective heat-transfer coefficients result in approximately proportional changes in the required heating intensity for de-icing. This serves to illustrate the importance of knowledge of the exact values of the heat-transfer coefficients prevailing over the propeller blade, especially in

the region of ice formation, where the heat-transfer coefficients exert the major influence on heat requirements.

<p style="text-align:center">Analysis of Values of Heating Intensity
·Required for De-Icing</p>

A review of the values of heating intensity required for de-icing as indicated by the data of this report show the values to be generally higher than the heating-intensity value of 8 watts per square inch, commonly in use. General agreement exists, however, between the heating-intensity values presented herein for the conventional blade shoe operated at a 20-second heating time and 0° F air temperature, and the value of 10 watts per square inch recommended in reference 1 for similar operating conditions.

An examination of the data taken at 8 watts per square inch (fig. 9) and a heating-time duration of 20 seconds (typical of operational values of heating intensity and heating time commonly in use) shows that complete protection can be expected with a conventional blade shoe operating under these conditions down to an air temperature of about 10° F, with only partial protection provided below this temperature down to about -5° : at which point no further de-icing can be expected.

In order to obtain a rough check of the values of heating intensity presented in this report, a comparison was made of values of heating intensity shown to be required in the investigation of reference 1 and values extrapolated from the data of the present report for the same operating conditions. Three cases from reference 1 were chosen in which the conditions were closest to those simulated herein. The data were obtained from reference 1, utilizing photographs showing the radial extent of residual ice formations to establish the position of marginal de-icing protection. These photographs, combined with the information on blade-shoe construction and meteorological and operating conditions, provided means for extrapolation of the heating-intensity values of this report. The results of this comparison are given as follows:

Figure No. (reference 1)	Duration of heat-on time (sec)	Heating intensity $(w/in.^2)$	
		Reference 1	Extrapolated from data of this report
19(a)	24	6.5	7.9
20(a)	12	8.0	9.1
20(b)	24	8.0	8.0

This general agreement is considered to be good, especially in view of
the rather extensive extrapolations involved, and serves to substantiate
the data presented in this report.

CONCLUSIONS

The following conclusions have been reached as the result of an
analytical study of cyclic de-icing with blade heating shoes mounted on
a hollow steel propeller. The percentage values of energy saving pre-
sented apply directly only to the case of hollow steel blades of approx-
imately the same configuration as that tested. However, the general
conclusions are applicable to all propeller blades fitted with external
heating shoes. All cyclic heating durations are based on a total cycle
time of 80 seconds.

1. Considerable saving of energy can be effected with blade shoes
currently in operation by applying higher heating intensities for shorter
durations of time than are generally in use. For the case of conventional
shoes of the type commonly used, by operating at a 5-second duration of
heating time, the total energy can be decreased to about 40 percent of
that required for operation at a 20-second heating duration.

2. Considerable saving of energy can be effected through proper
design of blade shoes. For example, if the thickness of the insulation
layer above the heater of a conventional blade shoe is decreased by a
factor of 2 and the thickness of the insulation below the heater is
doubled, the energy can be decreased to about 70 percent of that required
for a conventional shoe operated at the same cyclic ratios. Through
appropriate design and selection of insulating materials, the energy
requirement can be decreased to a value approaching 38 percent of that
needed for a conventional shoe operated at 5-seconds heating time.

3. The maximum heater temperatures reached under conditions of
efficient de-icing for the above cases are relatively independent of
heating intensity, and are well within safe limits of operation for exist-
ing insulation materials.

4. As the liquid-water content of the air stream increases, the
energy required to remove ice from the propeller decreases. Meteorological
conditions which impose the most stringent heating requirements on a
cyclically heated propeller are low values of liquid-water content together
with low air temperatures.

5. Uncertainties as to the exact values of convective heat-transfer
coefficient prevailing over the surface of the blade and ice layer result

in uncertainties of approximately proportional magnitude in the values
of required heating intensity.

h convective surface heat-transfer coefficient, Btu per hour, square foot, $^\circ F$

h_b blade-section maximum thickness, feet

J mechanical equivalent of heat, equal to 778 foot-pounds per Btu

L_f latent heat of fusion of ice, equal to 144 Btu per pound

L_s latent heat of sublimation of ice at temperature t_s, Btu per pound

M_a weight rate of water-drop impingement per unit of surface area, pounds per hour, square foot

p local barometric pressure, millimeters of mercury

q rate of heat flow per unit of surface area of the ice formation, Btu per hour, square foot

r temperature-recovery factor, dimensionless

R   thermal resistance of blade-shoe insulation material, ^{O}F per Btu,
           second

t_O ambient-air temperature, ^{O}F

t_s temperature of outer surface of ice layer, ^{O}F

U   speed of free stream with respect to propeller-blade section,
           feet per second

APPENDIX B

DEVELOPMENT OF EQUATION FOR CALCULATION OF HEAT TRANSFER

FROM THE SURFACE OF AN ICE LAYER DURING ITS FORMATION

During the formation of ice on an object traveling through a cloud composed of supercooled water drops, heat is transferred from the surface of the ice to the surrounding air at a rate determined by the individual rates of heat loss or gain resulting from convection, evaporation, impingement of the water drops, and release of the heat of fusion of the ice. This transfer of heat may be expressed by the following equation, which differs slightly from that derived in reference 2, where the positive terms represent the flow of heat from the ice to the surrounding atmosphere:

$$q = h\left(t_s - t_o - r\,\frac{U^2}{2Jgc_p}\right) + h\,\frac{0.622L_s}{pc_p}\,(e_s - e_o) - M_a\,c_{p_w}\,\frac{\dot{U}^2}{2Jgc_{p_w}} -$$

$$\left[\,M_a\,L_f - M_a\,c_{p_w}\,(32 - t_o) + M_a\,c_{p_i}\,(32 - t_s)\,\right] \tag{1}$$

Substituting appropriate values for the constants in equation (1) and collecting terms, the heat flow from the ice surface is given by

$$q = h\left(t_s - t_o - 8.33r\,U^2 \times 10^{-5}\right) + 2.6h\,\frac{L_s}{p}\,(e_s - e_o) +$$

$$M_a\left(0.47t_s - t_o - 127 - 2U^2 \times 10^{-5}\right) \tag{2}$$

Values of the effective coefficients of heat transfer from the surface of the ice were obtained from the slope of the curve of q plotted as a function of t_s as established by equation (2) for each segment of the ice formation. Since these curves showed very nearly a linear variation of heat transfer from the ice surface with ice-surface temperature, fixed values of electrical resistance were used in the analogue simulation of the thermal resistance to this heat flow. Values of equilibrium surface temperature for each segment were taken from these curves at the point where q equalled zero.
